## Abstract

*Very Early draft version. Comments welcome.*

Recent work argues that the Federal Reserve is not politically indifferent (Clark and Arel-Bundock, 2011). The Fed tends to choose looser monetary policies during Republican administrations, possibly in order to ensure the (re)election of ideologically preferred administrations. This model excludes an essential aspect of monetary policy decision-making: expectations about future inflation. We use the Fed's Green Book forecasts to test whether the partisanship of a government shape the estimates of future economic performance that influence FOMC policies. We find that Federal Reserve staff probably do not bias their forecasts to influence Fed governors around elections. However, they do systematically overestimate inflation during Democratic presidencies and underestimate inflation during Republican ones. This suggests that while not electorally motivated, Fed staff have a partisan bias when making inflation forecasts.

**Keywords:** forecast bias, Federal Reserve, rational partisan cycle,

Recent work argues that the Federal Reserve is not politically indifferent Clark and Arel-Bundock (2011). The Fed tends to choose looser monetary policies during Republican administrations, possibly to ensure the (re)election of ideologically preferred administrations. This bias is assumed by Clark and Arel-Bundock to arise from a Board of Governors that prefer rightist presidents to leftist ones and so set interest rates to help Republican incumbents and hinder Democratic ones.

\*[gandrud@yonsei.ac.kr](mailto:gandrud@yonsei.ac.kr)

†[cgrafstr@umich.edu](mailto:cgrafstr@umich.edu)

However, the Board of Governors makes monetary policy based on information provided to them by Federal Reserve staff about the future of the economy. If Fed staff expect higher inflation under Democrats than Republicans, these beliefs would be incorporated into the forecasts used by the Board of Governors to make policies. Thus partisan bias on the part of the Board of Governors is not necessary to produce the partisan cycles in interest rates observed in Clark and Arel-Bundock (2011).

We provide evidence that Fed internal inflation forecasts consistently predict that inflation will be lower than it turns out to be under Republican presidencies and predict that inflation will be higher than it turns out to be under Democratic administrations. Even accounting for changes in monetary policy, Federal Reserve economists over-shoot inflation for Democrats and under-shoot for Republicans. We expound a partisan heuristic model of policy expectations that explains these predictive failures.

In this paper we first provide a brief discussion of what inflation forecasts and forecast errors are, including their importance for monetary policy-making and our current understanding of how they are made. As we demonstrate in this first section, academic scholarship up till now has not examined possible partisan causes of forecast errors. We then introduce the issues of inflation forecast partisan biases and posit a number of ways that Green Book forecasting may be influenced by them. We test these theories with a series of regression models using both unmatched and matched data on Green Book inflation forecast errors from the 1970s through 2005. The models suggest that, even when controlling for a number of important economic and political factors, Green Book forecasts show a distinct presidential partisan bias.

## 1 Forecasting Inflation at the Fed

In this section we briefly describe what Green Book inflation forecasts and forecast errors are, why they are an important part of monetary policy-making in the United States, and the current understanding of how Federal Reserve inflation forecasts were made since the late 1960s.

### 1.1 Forecasting & Forecasting Errors

Prior to every meeting of the Federal Open Market Committee (FOMC - the primary policy-making body of the Federal Reserve) Federal Reserve staff create a document called the “Current Economic and Financial Conditions” or “Green Book” that contains information on recent behavior and forecasts of various macroeconomic aggregates.<sup>1</sup> The Federal Reserve staff produces forecasts of various elements of the US and global economies so that the FOMC can make policies appropriate to fulfill the Fed’s

---

<sup>1</sup>Green Book data can be found at <http://www.phil.frb.org/research-and-data/real-time-center/greenbook-data/philadelphia-data-set.cfm>. Accessed December 2011.

dual mandate of maintaining output growth and price stability. We focus on GNP/GDP price index forecasts in our study.<sup>2</sup> We choose this indicator of Federal Reserve forecast accuracy both because there is a strong theoretical assumption that central bankers are more inflation averse than are politicians (Cukierman, Webb and Neyapti, 1992) and because this is the dominant measure of forecast errors used in the economic literature (c.f. Romer and Romer, 2000). The FOMC uses these forecasts to determine the appropriate monetary policy to pursue. Higher inflationary expectations increase the likelihood of the FOMC tightening policy in order to slow inflation and an overheating economy; low inflationary expectations increase the likelihood of a loosening of monetary policy to bolster growth and employment, *ceteris paribus*.

Green Book forecasts are available for each quarter from the fourth quarter of 1964 through the end of 2005.<sup>3</sup> It is important to note that finalized forecasts of macroeconomic aggregates are a combination of both econometric models and the professional opinions of forecasters about likely changes in the economy’s trajectory not necessarily picked up in these models (Karamouzis and Lombra, 1989; Reifschneider, Stockton and Wilcox, 1997). The forecasts contained in the Green Book are the “consensus” forecasts combining **both** econometric models and judgmental forecasts assuming current monetary policies remain unchanged. Below we briefly explain how the econometric aspects of these “consensus” forecasts have been modeled.

## 1.2 Our Current Understanding of Fed Inflation Forecasting

Federal Reserve staff have used two primary sets of econometric models used during our observation period to forecast inflation, as well as other aspects of the US and global economies.<sup>4</sup> This section describes these two models and their importance for our understanding of forecast errors. It is important to reiterate that finalized forecasts of macroeconomic aggregates are a combination of both these mathematical models and the professional opinions of forecasters about likely changes in the economy’s trajectory not necessarily picked up in these models (Karamouzis and Lombra, 1989; Reifschneider, Stockton and Wilcox, 1997; Taylor, 1997). The most significant change was the move to the so-called Federal Reserve Board (FRB) Models in the mid-1990s that incorporated rational, as opposed to adaptive, expectations by market actors. We discuss the early and current models followed by the implications each has for predicted forecast errors.

---

<sup>2</sup>Note: GNP was used through 1991 (inclusive) and GDP was used from 1992 onward. Furthermore, the implicit deflator was used before the second quarter of 1996 and chain-weighted price index was used from the second quarter of 1996 on-wards.

<sup>3</sup>There is a five year lagged release schedule.

<sup>4</sup>This subsection draws heavily on Brayton et al.’s (1997) detailed description of the changes to Federal Reserve forecasting models that took place in 1996. See Brayton et al. 1997 for further details.

**Early models of the economy** The first simultaneous equation model of the US economy was developed and adopted by the Federal Reserve between 1966 and 1975. The model, originally developed in conjunction with MIT, University of Pittsburgh, and the Social Science Research Council (MPS), was based on a neo-classical growth model of production and factor demands and embraced the IS/LM/Phillip's Curve paradigm. This model was composed of more than XYZ equations modeling various interdependent aspects of the American economy in a simultaneous equations framework. Homogeneity assumptions ensured neutrality of money in the long-run—that is, changes in the stock of money only affects nominal variables in the economy such as wages or prices but these changes have no effect on real (inflation adjusted) variables like real GDP or employment in the long-run because any increase in the money supply will be offset by a proportional increase in prices and wages eventually. The essential feature of this model, however, was that the public held **adaptive expectations**. Basing a model on adaptive expectations means that people's expectations about what will happen in the future is based on what happened in the past. These models simply extrapolated future behavior of the economy from its recent past behavior, taking no account of the fact that people may change their behavior in response to future expected outcomes.

The collapse of Bretton Woods spurred a number of changes to the model. First, following the introduction of floating exchange rates the trade and exchange rate sections of the domestic economy were expanded. Second, and more significantly, an explicit model of the global economy was developed. The Multi-Country Model (MCM) introduced in 1975 originally included estimates of macroeconomic performance in the US, Canada, Germany, Japan, the UK, and “the rest of the world sector.” This model, which included both estimates of American consumption and production but then fed into equations of American consumption and production. This model was again based on the short-run dynamics of the IS/LM/Phillip's Curve and long-run neo-classical growth model. *~~~~~ some edits*

Both the MPS and MCM models were tweaked during the 1980s, with about one-third of the equations in the MPS model changed during this time. The MCM was also expanded to include a larger set of major trading partners.<sup>5</sup> However, the basic assumptions of the models, specifically the adaptive expectations assumptions, remained unchanged. The exclusive use of VAR models (solely backwards looking actors) meant that the models failed to explicitly account for actors concerns about future outcomes. The rational expectations revolution in economics in the 1970s and 1980s made this assumption an increasingly controversial one. Thus, the development of new models began in earnest in 1991.

**Current models of the economy** New models of the American economy's near-term trajectory replaced the MPS in 1997. The Federal Reserve Board US model (FRB/US) is composed of approximately

<sup>5</sup>The post-1992 model included each of the G-7 countries individually as well as Mexico, and blocks representing the OECD, newly industrialized countries, OPEC and the rest of the world.

I'm a little confused by this sentence

40 behavioral equations, estimated with single-equation techniques. This model explicitly considers the role of economic expectations in economic behavior. The foundational assumption of adaptive expectations in the old MPS model was thus replaced with **rational** or **model-consistent expectations**. In these models, prices are sticky and aggregate demand determines short-run output. Further, monetary policy's effects on the economy are extensively modeled.

The Federal Reserve Board Global (FRB/Global) model's development began in 1993 and had replaced the MCM by 1996. The FRB/Global model links the behavioral equations of FRB/US with approximately 200 behavioral equations representing the other 11 regions of the model. Anticipated values of future variables directly influence interest and exchange rates, components of aggregate demand, wages and prices.

**Models and their effects on predicted forecast accuracy** The innovations in how the Federal Reserve Board generates estimates of future economic performance (including changes to how they incorporated the effects of expected Fed interest rate policies has one important implication for forecast errors. Most notably, the move to rational expectations ought to improve forecast accuracy relative to the earlier period. The goal of incorporating forward looking actors into the models was to account for an important source of endogeneity in the earlier models that would lead to overestimates of important economic indicators under some circumstances and underestimates of those same indicators under others. None of these over- or under-estimates, however, ought to have been linked to the party of the president. We would, however, expect that forecast errors' absolute magnitude will be smaller after 1996 than in the earlier era.

discussion

### 1.3 Forecast accuracy

It is the accuracy of these forecasts that is of interest in this study. We measure accuracy as the forecast error, calculating **forecast error**  $E$  as the difference between the Green Book inflation forecast  $F$  for a given quarter  $q$  and actual inflation  $I$  as a proportion of actual inflation

$$E_q = \frac{F_q - I_q}{I_q} \quad (1)$$

We put the error in terms of actual inflation to control for the fact that mean actual inflation varies considerably across different periods (see Figure 1). An error of one percentage point is a significantly larger mistake when inflation is running at 3% than when it is running at 13%. Further, this measure allows us to incorporate forecasts from both the pre- and post-1997 era into a single model when we would expect systematically smaller errors in the latter period due to changes in how the Fed estimated

Figure 1: Green Book Inflation Forecasts and Actual Quarterly Inflation

Forecasts were made two quarters beforehand.

The grey dotted lines indicate the *approximate* years that the Simultaneous Equation Models (SEM) and Federal Reserve Board Global (FRB/Global) forecasting models were fully implemented.

inflation.

If the forecasts are unbiased then the mean error of the forecasts would be indistinguishable from zero. While the Federal Reserve’s internal forecasts meet this requirement over the history of Green Book forecasts (Romer and Romer, 2000), such an amalgamation disguises long periods of over- or under-predicting inflation, as noted in Capistrán (2006) and can be seen in Figure 1. Within economics the Fed’s forecasts have been examined for evidence of rationality. These studies have rarely incorporated political preferences of the Fed because Federal Reserve staffers are assumed to be politically independent, even if the voting behavior of the FOMC members may not be (Clark and Arel-Bundock, 2011).

We have 161 forecast quarters in our data set, spanning the first Green Book’s production in June 1964 through the end of 2005. Forecasts correspond to the FOMC meeting closest to the middle of the quarter. For a given quarter the data includes forecasts made in the present quarter and up to 5 quarters before. Actual inflation corresponding to each of these quarters<sup>6</sup> was found using data from the Federal Reserve’s FRED website.<sup>7</sup> Absolute actual inflation for each quarter and inflation forecasts made two quarters before are compared in Figure 1. In general we use forecasts made two quarters before.<sup>8</sup>

<sup>6</sup>Inflation was calculated by comparing quarters year-on-year. The exact inflation measure that the Federal Reserve was forecasting changed a number of times, so the measure of actual inflation used to create the forecast error variable changes accordingly. The GNP deflator indicator is used from the beginning of our sample through the end of 1991. From the first quarter of 1992 through the first quarter of 1996 actual inflation is measured with the GDP deflator. From the second quarter of 1996 we use the chain-weighted GDP price index.

<sup>7</sup>See <http://research.stlouisfed.org/fred2/>. Accessed December 2011.

<sup>8</sup>Using these two quarter forecasts constricts our observations to 150 since, apart from the first quarter of 1968, two quarter forecasts are not included in the Green Book data before the fourth quarter of 1968.

Figure 2: Inflation Forecast Errors (1969 - 2005)

Note: An error of 0 indicates that inflation was perfectly predicted.

The grey shaded box indicates minimal error, i.e.  $\pm 0.1$ .

#### 1.4 Partisan Forecast Errors?

As stated above, ideally forecasts should be unbiased in that they have a mean error of zero (Brück and Stephan, 2006, 5). Using this criteria, forecasts errors should be the same—ideally with a mean of 0—regardless of the incumbent president’s party identification. Looking only at forecast errors and the United States president’s partisan identity, is it plausible that there is a partisan bias to Green Book inflation forecasts? Figure 2 plots forecast errors across our sample. We’ve shaded out errors made between  $\pm 10$  percent of actual inflation. These could be considered relatively minimal errors.

The first thing to note is that inflation was almost never underestimated during the three Democratic presidential terms in our sample. Also, the largest overestimates were made during Clinton’s (Democratic) presidency. All of the major inflation underestimates were made during Republican presidencies, particularly during Nixon’s, Ford’s, and George W. Bush’s presidencies. Inflation was often overestimated during the second part of Reagan’s first term, his second term and George H.W. Bush’s term. Though it is important to note that over this period—often referred to as the Volcker Revolution (see Bartels, 1985)—inflation was much lower than before, as we can see in Figure 1.

This summary examination of inflation forecast errors suggests that there might be partisan biases. Before jumping into a further empirical investigation of these errors, we discuss why we might expect the Fed to experience partisan bias.

## 2 Possible Explanations of Partisan Biases in Fed Inflation

In this section we try to understand trends in Fed inflation forecast errors by discussing theories from the the political economy literature that provide alternative explanations of why forecasts seem to have a partisan bias. There is an extensive literature looking for partisan effects in monetary policy, but no studies examining the impact of presidential partisanship in predictions of inflation. Studies looking for evidence of partisan preferences manifesting themselves in the monetary policies chosen by the FOMC. There are two essential reasons that partisan effects would be found in policy: either a preference for one party over another by members of the FOMC or an expectation that the parties will engage in systematically different policies that will influence inflation, and so the Fed supports more preferred policies and attempts to inhibit less preferred ones.

The preference arguments assume that a conservative central banker will prefer the election of politicians who hold more similar inflationary preferences (those with a stronger preference for low inflation). In this US, this would lead to an assumption that the Federal Reserve would implement policies that supported the electoral prospects of Republican incumbents and harm the electoral prospects of Democratic incumbents (Clark and Arel-Bundock, 2011; Hakes, 1988; Sieg, 1997; Tootell, 1996).

The rational partisan expectations literature assumes that central bankers do not have an innate preference for one party over another, but instead expect Democrats and Republicans to behave differently in office Hibbs (1994). It is these behavioral expectations that would lead to different monetary policy outcomes under Democratic and Republican presidencies with the former engaging in more expansionary and inflationary policies than the latter. In order to stave off a rise in inflation under a Democratic presidency the Fed would tighten monetary policy (raise interest rates or reduce the money supply); because Republicans expected to prefer low inflation, they will pursue low inflation policies and so the FOMC can accommodate the President's policies without fear of stoking inflation. This argument is again based on the assumed preferences of partisans, but does not require the FOMC to be politically biased as the former does.

Arguments similar to those in the literature on partisan monetary cycles can similarly predict differences in inflation forecasts. We present three theoretical arguments about how inflation expectations would differ by the President's party: the partisan preference theory, the monetary expectations theory, and the partisan heuristics theory. Of the three, we find the partisan heuristics theory to be both most consistent with the data and the most reasonable.

The **partisan preference theory** is similar to the partisan preference model of monetary policy described above. This theory assumes that Fed staff have a preference for more inflation averse politicians to control the executive and so produce inflation forecasts that would justify the implementation of easy

monetary policy under Republican administrations and tight money under Democratic administrations, particularly as presidential elections approach. The FOMC, choosing policy based on these forecasts would then implement monetary policies to optimize its utility function, which would not need to depend upon presidential partisanship. This implies that inflation realized inflation would be higher than forecast during Republican presidencies and lower than forecast for Democratic presidencies. These effects would be particularly pronounced in the quarters running-up to elections as the Fed staff attempts to help its favored political party. Further, accounting for actual changes in monetary policy ought to increase the magnitude of partisan effects. This is because predictions of inflation during Republican presidencies, for example, will be lower than what the staff actually expects. If looser monetary policy is implemented in response to these low inflation forecasts than would have been chosen under the staff's true inflationary expectations, inflation will actually be higher than the staff's original "true" forecast.

The **monetary expectations theory** is based on a belief held by Federal Reserve economists that the members of the FOMC will engage in partisan monetary policy by lowering interest rates under conservative administrations and increasing them under liberal presidents. In this formulation, the Fed staff has no preference for one party over another, but knows that the FOMC does and so formulates estimates in order to counter the FOMC's policies (Clark and Arel-Bundock, 2011). If Fed economists believe that the Open Market Committee will choose higher interest rates during Democratic presidencies and vice versa for Republicans, then, assuming they are interested in the implementation of optimal monetary policies, they would produce forecasts that are higher than expected during Republican administrations and the lower for Democrats (the opposite of what was expected in the partisan preference theory above). If the FOMC fails to note the compensation made by the Fed staff, then we would expect that after accounting for policies implemented inflation forecasts would be higher than or equal to realized inflation during Republican terms and lower than or equal forecast under Democratic administrations.

If the FOMC anticipated these compensatory biases in staff forecasts, then the FOMC would discount the Green Book estimates and continue to implement inflationary policies during Republican administrations and contradictory policies during Democratic ones. This would result in approximately correct inflation forecasts for both Republicans and Democrats.

Finally, the **partisan heuristics theory** proposes that Fed staffers incorporate a simple heuristic about the policy behaviors of the parties and the effects these different policies will have on the economy. In this theory, economists at the Fed expect that Democrats and Republicans to behave differently in government and so formulates inflationary expectations with that belief in mind. Believing that the policies implemented by Democrats to be more inflationary than those implemented by Republicans, Democrats would be expected to produce more inflation and they would produce more inflation the more they spend, *ceteris paribus*. This model does not require those formulating forecasts be conscious

of their bias, but simply for it to work its way subtly into forecasts, particularly in the subjective aspect of the “consensus forecast” put forth in the Green Book. Further, because this bias would not need to be conscious, they might never notice this unintentional but systematic bias (as mistakes could occur for any number of economic reasons that they have been trained to consider) and so never correct it in future estimates.

### 3 Research Methods

We use non-matched and matched data sets with a number of parametric models (see Ho et al., 2007) to assess whether or not there are partisan biases in Green Book forecasts. This section discusses the choice of methods and variables. The following section discusses our results.

#### 3.1 Matching & Models

We are interested in disentangling the effects of presidential party ID and elections from the many background factors, such as economic shocks and FOMC policy changes, that might create inflation forecast errors. We treat presidential partisan identification and elections as ‘treatments’. Democratic presidencies are considered to be treatments. Republican presidencies are ‘controls’. The election quarter when an election is held and the quarter before it are considered treatments and all other quarters are controls. Of course, given that we are working with observational data, other variables that have an impact on forecast errors may have different distributions across the treatment and control groups (Diamond and Sekhon, 2012; Cochran and Rubin, 1973). This makes it difficult to identify the relationships between presidential party ID, elections and errors from all of the confounding background variables.

To address this issue we follow the advice of Ho et al. (2007) to pre-process our data with matching to create data sets where the distributions of confounding variables are more even across treatment and control groups. We then run our parametric analyses with the matched data sets. To do this we used the R package `MatchIt` (Ho et al., 2011) to create two matched data sets where the non-treatment covariates in the control groups closely matched with those in the treatment groups. Doing this helps us isolate the effects of these two ‘treatments’ from that of the background covariates.

Formally, each unit  $i$  in the data set is ‘assigned’ to either the treatment group ( $t_i = 1$ ) or the control group ( $t_i = 0$ ).  $y_i(1)$  is the potential outcome—in our case the inflation forecast error—for unit  $i$  of being in the treatment group, regardless of whether or not it was observed to be in this group.  $y_i(0)$  is the potential outcome if  $i$  was not in the treatment group, regardless of its observed assignment. It is impossible to observe both  $y_i(1)$  and  $y_i(0)$  at the same time. Instead we observe one version of  $y_i = t_i y_i(1) - (1 - t_i) y_i(0)$ . For each  $i$  there is a fixed vector of exogenous confounders  $X_i$ . Ideally  $t_i$  and

$X_i$  are independent. However, this is not necessarily the case. The point of matching is to reduce or eliminate the relationship between  $t_i$  and  $X_i$  by selecting, dropping, and/or duplicating data. Ideally this process matches one treated unit with one controlled unit that has the same values of  $X_i$ , i.e. the distribution of covariates is the same in the treated and control groups (Ho et al., 2011). This is known as “covariate balance” (Diamond and Sekhon, 2012, 1). Using matching to balance a data set “break[s] the link between the treatment variables and the pre-treatment controls”, effectively replicating the conditions of a randomized experiment with observational data (Ho et al., 2011, 2–3).

Balance is usually achieved in matching through propensity scores; the probabilities that unit were assigned the treatment given the covariates. The propensity score model is generally unknown (Drake (1993)). To find the propensity score model we use Diamond and Sekhon’s (2012) genetic matching method (GenMatch).<sup>9</sup> GenMatch uses an evolutionary search algorithm to automate the search for the propensity score model that creates maximum balance.

### 3.2 Parametric Models

Once we had created our matched data sets we used two types of parametric models to examine the effects of our treatment variables on the continuous inflation forecast error. The first was ordinary least squares linear regression (i.e. OLS).<sup>10</sup> The other type was Bayesian normal linear regression<sup>11</sup> which is particularly useful for our limited sample as it makes “valid small sample inferences via draws from the exact posterior” (Imai, King and Lau, 2012, 38). Please see the **Zelig** manual for details about Bayesian normal linear regression (Goodrich and Lu, 2007). See also Imai, King and Lau (2008) for a discussion of how to combine non-parametric matching and parametric analysis in one research process. Because we used non-parametric matching methods, not only do we better isolate the treatments’ effect from those of the background variables, but we also reduce our estimated causal effects’ dependence on the type of model we choose (Ho et al., 2007, 200–201).

Our generic parametric model we used is given by

$$E_q = \alpha + \beta T_q + \beta X_q + \epsilon, \quad (2)$$

where  $T_q$  is the treatment for quarter  $q$  and  $X$  is a vector of covariates.

---

<sup>9</sup>The method is implemented with **MatchIt**. The original source code for the exact matching models can be found at <https://github.com/christophergandrud/GreenBook/blob/master/Analysis/MainAnalysis2.R>.

<sup>10</sup>In **Zelig** this is the **ls** model.

<sup>11</sup>In **Zelig** this is the **normal.bayes** model.

### 3.3 Variables

In Section 1 we discussed our dependent variable—inflation forecast errors. We are interested in seeing how US presidents’ partisan identity and the existence of an upcoming presidential election affect these errors. So, we created **president party identification** and **election period** variables. The president party ID variable is 1 when the president is a Democrat and 0 when they are a Republican. Since forecast error data is released on a quarterly basis, we consider a president to be sitting from the first quarter after the election.<sup>12</sup> We consider quarters to be in the election period either if the presidential election is held in that quarter or the quarter before.<sup>13</sup>

To further examine whether or not Federal Reserve staff were taking into consideration an electoral business cycle, we include a variable of the **quarters until the presidential election**. This simply counts down from the quarter after the previous election.<sup>14</sup> The quarters that included presidential elections were coded as 0.

The United States president does not set the level of government expenditure—one of the main non-monetary policy causes of inflation—by themselves. Instead, the president is constrained by the two houses of Congress. To examine whether or not Federal Reserve staff are taking into consideration the partisan composition of Congress as well as the president’s party identification, we include variables of **Democratic legislators as a proportion of Republican legislators** in the House of Representatives and the Senate. Data on the number of legislators with Republican and Democratic party IDs was found at infoplease.<sup>15</sup>

There are at least three possible ways that Congressional party identification may affect forecast errors. The first is a simple circumstance where Federal Reserve staff with rational partisan expectations pay attention to the partisan control of a chamber of Congress *independent of* the president’s party identification. For example, Fed staff could predict higher spending if Democrats control one of the houses of Congress even if they do not control the other house or the presidency compared to a situation where all parts of the executive and legislature were controlled by Republicans. This might lead to higher inflation error.

Though they make different predictions, both of the latter two ways that partisan control of Congress may affect inflation forecasts are through interactions with presidential party identification.

The first interaction theory is that Federal Reserve staff with simple rational partisan expectations would presumably expect that a Democratic president would be able to get policies closer to their ideal

---

<sup>12</sup>Elections are held almost at the midpoint—early November—of an election year’s fourth quarter. Presidents are sworn into office near the beginning—20 January—of the following year’s first quarter.

<sup>13</sup>If  $q_e$  is a quarter with an election then we code quarters  $q_e$  and  $q_{e-1}$  election quarters.

<sup>14</sup>There are 15 quarters before a United States presidential election quarter.

<sup>15</sup>See <http://www.infoplease.com/ipa/A0774721.html>. Accessed May 2012.

point when there is a Congress with similar preferences. If a Democratic president had chambers of Congress controlled by Democrats, presumably Federal Reserve staff would expect even higher fiscal expenditures and therefore even higher inflation. Conversely, Republican presidents with a Republican-controlled Congress may be even better at cutting spending, leading to lower inflation.

The second interaction possibility is based largely on Krause’s (2000) work about the affect of partisan divisions on fiscal deficits in the United States. He finds partisan fragmentation can play a role in increasing Federal deficits. Higher political conflict, he argues, “results in equilibrium fiscal outcomes that favor greater spending and/or a willingness to lower taxes since politicians will exhibit a greater proclivity in providing voters with program benefits and to delay its payment” (Krause, 2000, 542). Because of this pro-deficit bias Federal Reserve staff may anticipate higher government borrowing when the presidency and houses of Congress are controlled by different parties.

If biases are largely the result of misspecified economic forecasting models we would expect errors to decrease overtime as the models improved. In particular, we would expect this fall in errors to occur specifically around 1996 when the Federal Reserve Board’s new Global Behavioral Equation Model was introduced. To examine this we include a **FRB/Global Model** dummy variable. It equals one for all quarters from and including the first quarter of 1996. It is zero otherwise.

Green Book forecasts are based on the assumption that monetary policy will not change between when the prediction is made and the time period it is predicting. Forecast errors may occur if monetary policy changes. Maybe this produces a negative relationship between forecast errors and monetary policy decisions. If the FOMC raises interest rates then inflation may decline, causing the original forecast to have been too high and vice versa. To control for monetary policy changes we include a variable of **relative changes to the discount rate** from the quarter the Green Book prediction was made to the quarter it is predicting.<sup>16</sup> The discount rate is one of the Federal Reserve’s main tools for influencing the interest rate, especially the Fed funds rate.<sup>17</sup>

To examine if Federal Reserve inflation forecaster errors are affected by actual levels of government expenditure we included the percentage of **current government expenditure to GDP** and **government debt to GDP**.

To examine how broader economic factors may be related to forecast errors we include variables of **GDP output gaps** and **recessions**. The former is simply potential GDP as a percentage of real GDP.

---

<sup>16</sup>We averaged the discount rate over each quarter. Then we used the average discount rates  $D$  in each quarter  $q$  to create the variable  $\Delta D$  using the simple formula:  $\Delta D = \frac{D - D_{q-2}}{D}$ . Note that the Federal Reserve changed how it used the discount rate and referred it at the beginning of 2003. To address this issue we primarily used data on the United States’ discount rate recorded by the International Monetary Fund through this time period. Their data only goes back to the fourth quarter of 1982. So, before that we use the discount rate. Both of these variables are found in the FRED database at the St. Louis Federal Reserve (see: <http://research.stlouisfed.org/fred2/> (accessed July 2012)).

<sup>17</sup>A similar **relative changes in the Fed funds rate** variable was included in some preliminary analyses. However, it did not change the results substantially and was estimated to have a similar effect on errors as the discount rate variable.

The latter is a dummy variable for whether or not the United States was in a recession. All of these variables are from the FRED database (Accessed June 2012) and are in nominal terms.

Finally, we include a variable for the sitting Federal Reserve Board Chair.<sup>18</sup>

## 4 Results

In this section we present results from multiple regression model specifications with both unmatched and matched data sets.

We primarily use visual methods as a diagnostic to determine if the covariates in the matched data sets were balanced. Almost all parametric model specifications are run with both the matched and unmatched data sets.<sup>19</sup> In all of the Bayesian regressions we use the `Zelig` default 1,000 MCMC burn-in iterations and 10,000 iterations after burn-in. We use the Heidelberg-Welch diagnostic to examine whether or not the Markov Chains converged to their stationary distributions.

We graphically present the key results in this section. Coefficient estimate tables for the models are given in the Appendix (see tables 1, 2, 3, 4, and 5). In general there is very little difference in the coefficients estimated using OLS and Bayesian linear regression models (see Figure 3). Usually more variables were ‘statistically significant’<sup>20</sup> in models from the unmatched data set compared to estimates from both matched data sets.

**Presidential Party Identification** Our main finding is that the—presidential party identification—had a strong positive association with Federal Reserve staff inflation forecast errors across all model specifications. This finding is what we would expect if Federal Reserve staff have a general presidential partisan bias and is very robust. For instance, the 95% confidence band around the coefficient estimate moves somewhat further away from 0—i.e. no relationship—when using matched data (see Figure 3).

These analyses provide strong evidence that Federal Reserve staff overestimate the effect Democratic presidents have on inflation compared to Republican presidents.

To get a sense of approximately how big this bias might be we simulated expected standardized forecast errors for Democratic and Republican presidencies, holding all other covariates at their means.<sup>21</sup> Results from these simulations can be found in Figure 4. We expect that on average the Fed overestimates inflation by 14 percent during Democratic presidencies. Expected average inflation error during

---

<sup>18</sup>Chairs for the years in our analysis are William McChesney Martin, Jr., Arthur Burns, G. William Miller, Paul Volcker, and Alan Greenspan.

<sup>19</sup>The Federal Reserve chair variable was not included in the matching models because some chairs in the pre-Volcker/Greenspan era were in office for very few quarters, making it difficult to match them.

<sup>20</sup>At the standard 0.05 significance level.

<sup>21</sup>1000 simulations were run on a normal Bayesian linear regression model matched by presidential party ID and including the same variables as those in Model C6 from Table 3.

Figure 3: 95% Confidence Bands for Coefficients from a Variety of Matching and Parametric Model Specifications

Intercept values are not shown to maintain a reasonable scale for comparing covariate estimates.

Republican presidencies of -20 percent during Republican presidencies. Clearly, at least between 1970 and 2005, Fed staff were overly pessimistic about Democratic presidents' effect on inflation and even more overly optimistic about Republican presidents' effect.

The estimated effects hold even when we control for actual government expenditure. This suggests that Federal Reserve staff are not simply responding to different levels of government spending that Democratic and Republican presidents may tend to initiate.

**Presidential Elections** We did not find any evidence that inflation forecast errors were associated with elections. This was true in parametric models using both unmatched data and matched data where the election period variable is the treatment. Estimates of the relationship between the quarters until election variable and forecast errors<sup>22</sup> also did not provide any evidence that inflation errors are related to elections.

Data limitations make it difficult to fully examine the extension of Clark and Arel-Bundock's (2011) election gaming approach to Federal Reserves staff.<sup>23</sup> Nonetheless, we attempted to examine this hypothesis with an interaction (not shown) of the president's party ID variable and both the election dummy and quarters to election variables. In all cases the president's party ID variable was robust whereas the

<sup>22</sup>This variable was obviously omitted from the models with the election period variable because they are highly correlated.

<sup>23</sup>We only have three Democratic presidential terms in our data, only two of which ended in the incumbent running for reelection.

Figure 4: Simulated Expected Inflation Forecast Error for Republican and Democratic Presidencies

From an OLS regression with data matched by presidential party identification. Variables included are the same as those in Model C6 from Table 3.

The figures show 1000 simulations per fitted value.

The solid line connects the two groups' means.

election variables and the interaction term were very statistically insignificant.

In this limited data set Fed Staff do not appear to be over estimating inflation when a Democratic president is running for reelection in an attempt to influence the FOMC to raise interest rates and lower the president's chances of winning. These findings have clear implications for how we understand the potential causes of Green Book partisan inflation forecast biases as well as FOMC interest rate decisions around elections. It seems that FOMC members, not their staff, are driving the increases in the Fed Funds Rate around elections when Democrats are in power that Clark and Arel-Bundock observed.

**Partisan Control of Congress** Might Federal Reserve staff be taking into consideration not only the president's party identification, but also the partisan composition of Congress? Across all of our data sets and parametric model specifications we find no evidence that the partisan composition of congressional chambers is related to inflation forecast errors.

We created parametric models with two-way and three-way interactions between presidential and congressional party identification to examine the two other ways we identified that presidential and congressional partisan ID might be related to forecast errors. All of the partisan interactions were generally statistically significant. To make substantive sense of these estimated interactions we use simulations, as above, to find expected inflation forecast errors at various levels of the presidential and congressional party identification. To highlight the findings, Figure 5 shows the results of simulations

Figure 5: Simulated Interactions between President Party ID and Congressional Party Controls

From an OLS regression with data matched by presidential party identification. Variables included are the same as those in Model C10 from Table 3. The figure show 1000 simulations per fitted value.

Both the House and Senate Democratic/Republican variables were set at 1.2 for Democratic congresses and 0.8 for Republican congresses.

The solid line connects the means of the congressional partisan control groups.

where the levels of partisan convergence and divergence are at their most extreme: one party control of all bodies compared to a situation where different parties control the presidency and Congress.<sup>24</sup>

The first thing we should notice in Figure 5 is how presidential partisan identification still seems to be driving the direction of the inflation forecast error: inflation is underestimated during Republican presidencies and overestimated during Democratic ones, regardless of partisan control in Congress. The estimated substantive effect of congressional control on forecast errors in the magnitude of the over or under estimates. In particular, inflation is very underestimated for Republican presidencies with Republican congresses. There may be an expectation among Fed Staff that these governments will cut expenditure much more than they actually do. Forecast error is slightly higher on average with Democratic presidencies and Republican congresses compared to when both are controlled by Democrats. This finding fits with a story where Fed Staff believe spending will be higher with a divided government. However the difference between the two means is small<sup>25</sup> and there is considerable overlap in the two groups of simulation results.

Despite some evidence for an interaction between congressional and presidential party identification, it

<sup>24</sup>Both the House and Senate Democratic/Republican variables were set at 1.2 for Democratic congresses and 0.8 for Republican congresses.

<sup>25</sup>There is a 12 percentage point difference between the two.

is not clear at this time how these results can be consistently explained across Democratic and Republican presidencies.

**Government Expenditure** Nonetheless, it seems that Federal Reserve staff may also overestimate the effect of government expenditure on inflation. This is indicated by a consistently positive and significant coefficient for the government expenditure variable, even when controlling for president's party ID.

**FRB Global Forecasting Model** The introduction of the FRB/Global behavioral equation forecasting model does not seem to have begun an era of significantly lower inflation forecasting error. In fact, across all of our matching and parametric model specifications, forecasts made after the introduction of this approach are not significantly different than those made before it.

**Changes to the Discount Rate** As expected, relative changes to the discount rate were often found to be negatively associated with inflation forecast errors. Increasing the discount rate could result in lower inflation than expected and vice versa. Controlling for FOMC policy did not affect the estimated relationship between presidential party ID and errors. Also, the results were not robust across all of the models.

## Discussion: Do Fed Forecasts Have a Partisan Bias?

FILL IN

MAYBE TALK ABOUT HOW IT IS STRANGE THAT ACTORS WITH "RATIONAL" PARTISAN EXPECTATIONS WOULD NOT UPDATE THEIR INFLATION EXPECTATIONS. I.E. WHY WOULD THEY CONTINUE TO BE WRONG ABOUT INFLATION GIVEN THE PRESIDENT'S PARTY ID?

# Appendix

## Replication

This paper was written with `knitr` (Xie, 2012). It can be entirely replicated from data, analysis source code, and markup files available as a `.zip` file downloadable from our GitHub page at: <https://github.com/christophergandrud/GreenBook/zipball/master>.

The recession variable is omitted because there was no variation in the matched data set.

The reason that there was no variation is because there was never a recession during an election period in our data set.
